

Quality Assessment of Surface Current Fields From TerraSAR-X and TanDEM-X Along-Track Interferometry and Doppler Centroid Analysis

Roland Romeiser, *Member, IEEE*, Hartmut Runge, Steffen Suchandt, Ralph Kahle, Cristian Rossi, and Paul S. Bell

Abstract—All existing examples of current measurements by spaceborne synthetic aperture radar (SAR) along-track (AT) interferometry (ATI) have suffered from short baselines and corresponding low sensitivities. Theoretically, the best data quality at X-band is expected at effective baselines on the order of 30 m, i.e., 30 times as long as the baselines of the divided-antenna modes of TerraSAR-X. In early 2012, we had a first opportunity to obtain data at near-optimum baselines from the TanDEM-X satellite formation. In this paper, we analyze two TanDEM-X interferograms acquired over the Pentland Firth (Scotland) with effective AT baselines of 25 and 40 m. For comparison, we consider a TerraSAR-X dual-receive-antenna (DRA)-mode interferogram with an effective baseline of 1.15 m, as well as velocity fields obtained by Doppler centroid analysis (DCA) of single-antenna data from the same three scenes. We show that currents derived from the TanDEM-X interferograms have a residual noise level of 0.1 m/s at an effective resolution of about $33 \text{ m} \times 33 \text{ m}$, while DRA-mode data must be averaged over $1000 \text{ m} \times 1000 \text{ m}$ to reach the same level of accuracy. A comparison with reference currents from a 1-km resolution numerical tide computation system shows good agreement in all three cases. The DCA-based currents are found to be less accurate than the ATI-based ones but close to short-baseline ATI results in quality. We conclude that DCA is a considerable alternative to divided-antenna mode ATI, while our TanDEM-X results demonstrate the true potential of the ATI technique at near-optimum baselines.

Index Terms—Interferometry, radar velocity measurement, remote sensing, synthetic aperture radar (SAR).

I. INTRODUCTION

ALITTLE more than 25 years ago, Goldstein and Zebker described the concept of ocean surface current measurements by synthetic aperture radar (SAR) along-track (AT) interferometry (ATI) and presented a first example result [1]. Since

then, the feasibility of current measurements by this technique has been demonstrated in a number of further experiments, using interferometric SAR (InSAR) systems on aircraft (e.g., [2]–[5]), on a space shuttle [6], [7], and on the first ATI-capable satellite, the German TerraSAR-X [8]. Furthermore, some theoretical studies have been performed to understand the ATI imaging mechanism of current and wave fields and to find out how the ATI data quality depends on radar frequency, incidence angle, AT baseline, etc., and what parameter combinations are most promising for accurate high-resolution current measurements (e.g., [9] and [10]). According to these studies, optimal AT baselines, defining the time lag between the two SAR images that form an interferogram, should be on the order of 20–30 m for satellite-based X-band ATI systems. Here, we always refer to the “effective” AT baseline, which is half the physical AT distance between the two antennas if only one of them is used for transmitting and both for receiving, as it is the case with the TerraSAR-X and TanDEM-X data considered in this work.

Unfortunately, the Shuttle Radar Topography Mission (SRTM) setup (used in [6] and [7]) and the divided-antenna modes of TerraSAR-X (explained in [10]–[12] and used in [8]) have offered effective AT baselines of only 3.5 m and approximately 1 m, respectively, resulting in a clearly suboptimal sensitivity to scatterer velocities and the requirement to average the interferograms over thousands of full-resolution pixels to reduce phase noise. This degrades the effective spatial resolution to several 100 m at best. In contrast to this, the AT baselines between the TerraSAR-X satellite (launched in June 2007) and its companion TanDEM-X (launched in June 2010) are too long over most ocean regions of interest: With the standard helical orbit pattern, the two satellites have an AT distance between 0 at the northern- and southernmost points of the orbit and about 550 m over the equator [13], limiting the region of useful baselines for intersatellite interferometry over water to narrow latitude bands far in the north and south. In regions of longer AT baselines, the data quality suffers from temporal decorrelation of the backscattered signal.

However, the TanDEM-X formation geometry gets modified from time to time to optimize the cross-track (XT) interferometry performance in certain regions or for certain applications. A setup used from January 12 through March 29, 2012, shifted the region of useful AT baselines to a latitude band that included the area around the Orkney Islands off the northern coast of Scotland [13]. The strait between the Scottish mainland and

Fig. 1. Map showing the northern part of Scotland and the Orkney Islands north of it, with a white arrow pointing at the Pentland Firth. Source: Google earth. The TerraSAR-X/TanDEM-X data sets were acquired on descending overpasses with a heading of 196° and a radar look direction of 286° .

the Orkney Islands, the so-called Pentland Firth, is a very good test site for current measurements, since the tidal currents at some locations can get as large as 5 m/s, which makes them attractive for renewable energy projects. Because of this, the flow conditions are relatively well known, and it is relatively easy to obtain reference data from *in situ* measurements and numerical circulation models for an evaluation of the ATI data quality. Furthermore, we already acquired ATI data in this area in the two divided-antenna modes of TerraSAR-X, the aperture switching (AS) and dual-receive-antenna (DRA) modes, in 2009 and 2010, such that a return to the Pentland Firth was a natural preferred choice for longer baseline ATI tests.

In the following, we analyze two interferometric TanDEM-X data sets acquired at the Pentland Firth on February 26 and March 19, 2012, and the data quality improvements with respect to a TerraSAR-X DRA-mode data set from April 26, 2010. In addition to the interferometry results, we consider current fields obtained by Doppler centroid analysis (DCA) of single-antenna data from all three cases. As reference, we use current fields from the numerical offshore tide computation system POLPRED. The available radar data sets and the processing steps for deriving line-of-sight surface current fields from the interferometric data are described in detail in the following section. In Section III, we compare the ATI-based line-of-sight current fields with corresponding POLPRED results. Section IV deals with the DCA technique and a comparison of DCA and ATI results. Final conclusions and an outlook are presented in Section V.

II. AVAILABLE DATA AND PROCESSING STEPS

Fig. 1 shows the location of the Orkney Islands and the Pentland Firth north of the mainland of Scotland. After a few experimental AS-mode data acquisitions over this area in late 2009, with very narrow swath widths on the order of 5 km, a first TerraSAR-X ATI data set of the Pentland Firth with the full swath width of 30 km was acquired in DRA mode on

April 26, 2010, at 06:41 Coordinated Universal Time (UTC; corresponding to 7:41 local time/British Summer Time at this time of the year). Almost exactly the same area is covered by the two TanDEM-X data sets from February 26 and March 19, 2012, again at 06:41 UTC (now equal to local time). All three scenes have a nominal incidence angle of 31° and a full-resolution pixel spacing on the order of $1.7\text{ m} \times 2.1\text{ m}$ (range \times azimuth). Some further acquisition parameters as well as wind speeds and directions at the times of the three satellite overpasses are provided in Table I. The wind information was taken from weather station data available at <http://www.wunderground.com>. The nearest weather station is the one at the airport of Kirkwall, the capital of Orkney, approximately 30 km north–northeast of the center of our test area.

A. TerraSAR-X DRA-Mode Data

The TerraSAR-X DRA-mode data set was acquired during a specific DRA-mode campaign in spring 2010. While the AS mode uses a single receiver chain for both antenna halves in an alternating manner, the DRA mode uses the main and backup receiver chains of the SAR system in parallel, such that the regular pulse repetition frequency can be used and each antenna half receives an image with the full stripmap swath width of 30 km [10]. The effective AT baseline in DRA mode is approximately 1.15 m. Unfortunately, our data set was acquired in horizontal (HH) polarization. We prefer vertical (VV) polarization for ATI over water, because of a stronger backscattered signal and a corresponding better signal-to-noise ratio [9].

The basic SAR processing and interferogram generation were performed at the SAR Department of the Institute for Remote Sensing Technology, German Aerospace Center (DLR), in Oberpfaffenhofen, Germany, using the optimized procedures described in [14]. The further analysis was done at the University of Miami, FL, USA. As a first step, the complex pixel values of the interferogram were averaged over grid cells of approximately $25\text{ m} \times 25\text{ m}$, corresponding to $15 \times 12 = 180$ original pixels per grid cell. At the same time, the magnitudes of the complex pixel values (interferogram amplitudes, i.e., products of two complex image amplitudes, dimensionally equivalent to image intensities) were averaged to obtain a reduced-resolution intensity image, and by combining the results of both averaging procedures, the coherence could be computed for each grid cell. In the next step, the phases of the reduced-resolution interferogram were converted into horizontal line-of-sight Doppler velocities, and a large-scale trend in azimuth direction was removed by fitting a quadratic correction function. Results are shown in Fig. 2. Note that the data are presented in image coordinates, i.e., the radar look direction is exactly from right to left in the figures. The detected Doppler velocities and all line-of-sight currents discussed in the following are aligned with this direction, with positive values indicating a motion from left to right. The compass cross within Fig. 2(a) shows how the images are rotated by approximately 16° with respect to the north–south direction.

At this spatial resolution, the Doppler velocities from DRA-mode data are still very noisy, and further averaging is

TABLE I
ACQUISITION PARAMETERS/CONDITIONS OF THE THREE CONSIDERED TERRASAR-X/TANDEM-X ATI DATASETS

Data Acquisition Time UTC	Instrument & Mode	Polarization	Look Direction	Effective ATI Baseline	ATI Time Lag	Incidence Angle	Velocity Range ^a	Wind Speed ^b	Wind Direction ^b
2010.04.26 06:41	TerraSAR-X DRA	HH	286°	1.15 m	0.15 ms	29.7–32.6°	199.90 m/s	6.2 m/s	240°
2012.02.26 06:41	TanDEM-X	VV	286°	24.35–25.77 m	3.17–3.36 ms	29.8–32.8°	9.14 m/s	4.0 m/s	225°
2012.03.19 06:41	TanDEM-X	VV	286°	39.48–40.90 m	5.14–5.33 ms	29.9–32.9°	5.69 m/s	5.1 m/s	190°

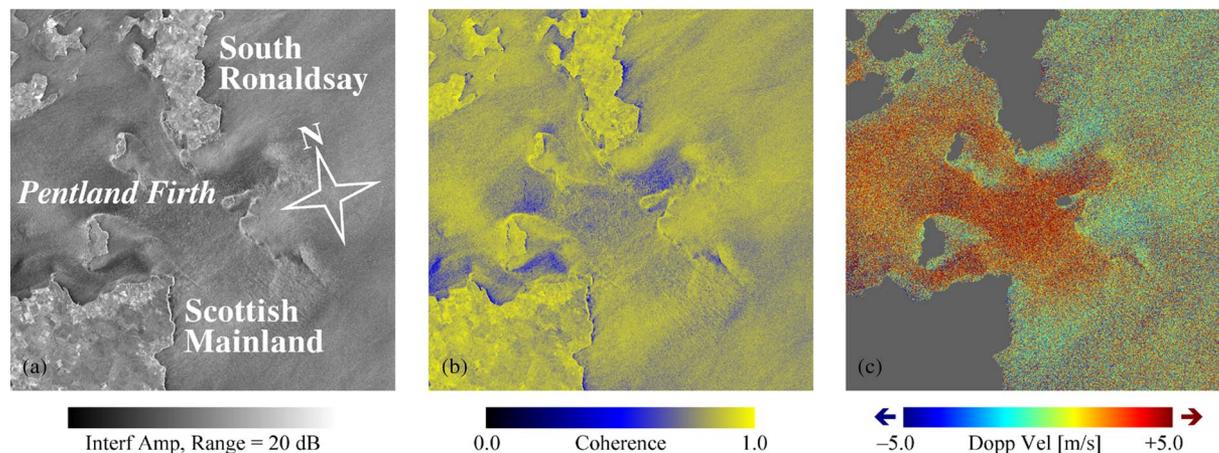

Fig. 2. Data from the TerraSAR-X DRA-mode overpass on April 26, 2010, 06:41 UTC, averaged over 25×25 m grid cells: (a) Interferogram amplitude, (b) coherence, and (c) interferogram phase converted into horizontal Doppler velocity. Shown area size $\approx 30 \text{ km} \times 30 \text{ km}$; radar look direction = from right to left; positive velocity direction = from left to right.

mandatory to obtain meaningful current estimates. The reader may be surprised to see so much phase noise in data with a quite good coherence (mean coherence over water within the vicinity of the Pentland Firth = 0.81). The explanation lies in the fact that, at such a short baseline, the shown horizontal Doppler velocity interval of 10 m/s corresponds to an ATI phase interval on the order of only $\pi/10$ or 18° (see column “Velocity Range” in Table I). Accordingly, the complex numbers in the original interferogram fluctuate around a relatively narrow phase range, which corresponds to high coherence. However, the fluctuations are dominated by instrument noise and not by contributions of actual scatterer velocity variations. This makes the Doppler velocities look noisy without further smoothing. As discussed in [10], the TerraSAR-X instrument has a relatively high instrument noise level, which has particularly negative effects on the ATI data quality at the extremely short baselines of the AS and DRA modes.

B. TanDEM-X Data

As discussed in [13], the TerraSAR-X/TanDEM-X orbit geometry used from January 12 through March 29, 2012, was suitable for current measurements at near-optimum AT baselines in the Orkney region. We were able to program two data acquisitions within the framework of a TanDEM-X science project, including some specific fine tuning of the satellite orbits to optimize the baselines. The resulting effective AT baselines were about 25 and 40 m, respectively, mapping horizontal velocity ranges of 9.14 and 5.69 m/s into a phase range of 2π (see Table I). At the same time, effective XT baselines on the order of 23–24 m caused mapping of a surface elevation range

of about 200–210 m into the same phase interval. Since the actual height variations within the sea surface are two orders of magnitude smaller than this, the topographic contributions to the detected phase variations will be neglected in our interferogram analyses. However, the XT baseline causes a mean phase offset, depending on the height of the sea surface with respect to a reference plane. This must be taken into account in the absolute calibration of derived velocities. Unlike our DRA-mode example, the TanDEM-X data were acquired at VV polarization.

Again, the basic SAR processing and interferogram generation for the two TanDEM-X cases were done at DLR, while all further processing and analysis were done at the University of Miami. Because of the unknown phase offset due to the XT baseline, we added an absolute calibration step in which the mean Doppler velocity and current at coastlines perpendicular to the radar look direction were forced to be zero. The same method was used to adjust the SRTM-derived current fields in [6] and [7], which suffered from exactly the same problem. To eliminate the effect of calibration issues from our comparison of different radar results with each other as well as with model results, we applied the same adjustment to the DRA-mode results in Fig. 2, and we adjusted the mean values of the DCA-based Doppler velocities and currents in Section IV such that they match the mean values of the corresponding ATI results (the DCA results do not include suitable coastlines for a calibration based on the coastline current criterion).

Fig. 3 shows the interferogram amplitudes, coherences, and Doppler velocities obtained after averaging over 25×25 m grid cells. In contrast to the DRA-mode data in Fig. 2, the TanDEM-X data show very clear signatures of surface currents

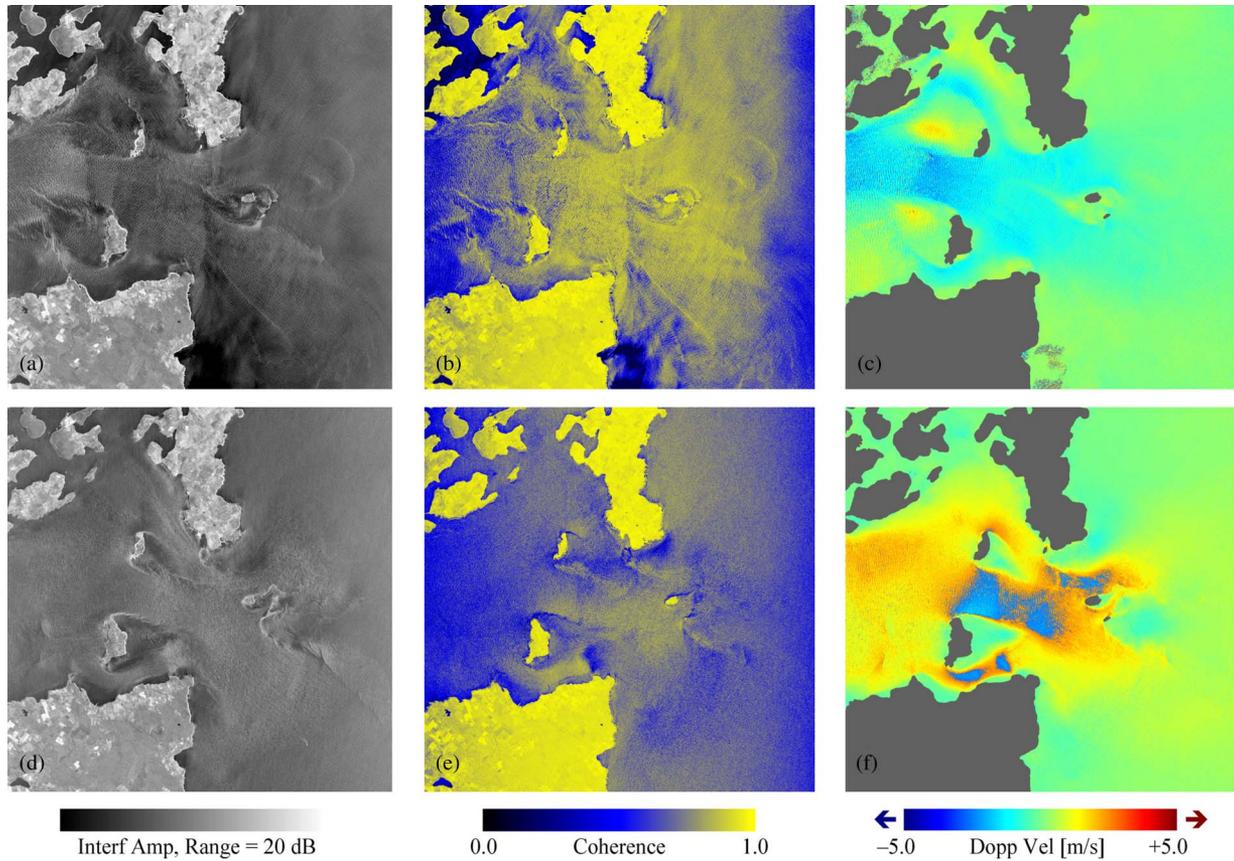

Fig. 3. Same as Fig. 2, but for TanDEM-X data from (top) February 26 and (bottom) March 19, 2012, both at 06:41 UTC. The artifacts in the center of (f) illustrate the effect of phase wrapping at long baselines, which can be easily corrected in this case.

at this resolution, despite lower mean coherence levels of 0.72 in the February 26 case and 0.68 in the March 19 case. The coherence decreases with an increasing AT baseline because of temporal decorrelation of the backscattered signal. However, at the same time, the phase contributions due to scatterer velocities get larger while the instrument-related phase noise stays constant, such that the signal-to-instrument-noise ratio improves. Together, the quality of the velocity measurement is much better at the near-optimum TanDEM-X baselines than at the short DRA-mode baseline because the better signal-to-instrument-noise ratio outweighs the negative effects of signal decorrelation. However, the coherence continues to decrease with further increasing AT baselines, making the data unsuitable for interferometry when it gets too low. Low coherence can also occur where the backscattered power from the sea surface gets close to or below the instrument noise level, such as in the area near the coast at the bottom part of Fig. 3(a)–(c) that exhibits a low image intensity and coherence and very noisy Doppler velocities.

Another issue at long baselines is phase wrapping. When the range of scatterer velocities in a test area gets larger than the range of velocities mapped into a phase interval of 2π , some phases wrap around the $\pm\pi$ point, such that large positive velocities appear as negative ones and vice versa. To correct this, one must identify the affected grid points and add or subtract the velocity of ambiguity, extending the total velocity range beyond the range mapped into $[-\pi, +\pi]$. We have a case

of phase wrapping in the center of the TanDEM-X scene from March 19, 2012, where the horizontal velocity in the center area is larger than the limit of 2.85 m/s. This area shows up in blue instead of red color in Fig. 3(f). Owing to the smoothness of the true velocity field, it is easy to detect the boundaries of the phase-wrapped area and to correct the problem.

C. Initial Data Quality Analysis

A closer look at Fig. 3(c) and (f) suggests that the Doppler velocities exhibit wave patterns that are correlated with the ones visible in the interferogram amplitude images in Fig. 3(a) and (d). Fig. 4 shows this in more detail for a magnified subsection of Fig. 3(a) and (c). For this purpose, the interferogram averaging was done over 5×4 original pixels only, resulting in a grid cell size of $8.40 \text{ m} \times 8.46 \text{ m}$. Indeed, there are clear and consistent wave patterns in the interferogram amplitude and phase signatures. The dominant waves have wavelengths on the order of 200 m. This demonstrates the high quality of the TanDEM-X data at the baselines used here. A detailed analysis of the wave signatures goes beyond the scope of this paper, but we will continue to work on it and present results on another occasion.

A quantitative comparison of the qualities of the TerraSAR-X DRA-mode and TanDEM-X data can be done by analyzing residual Doppler velocity fluctuations as a function of the number of averaged samples. We have done this for two homogeneous 4096×4096 pixel subsections of the full-resolution

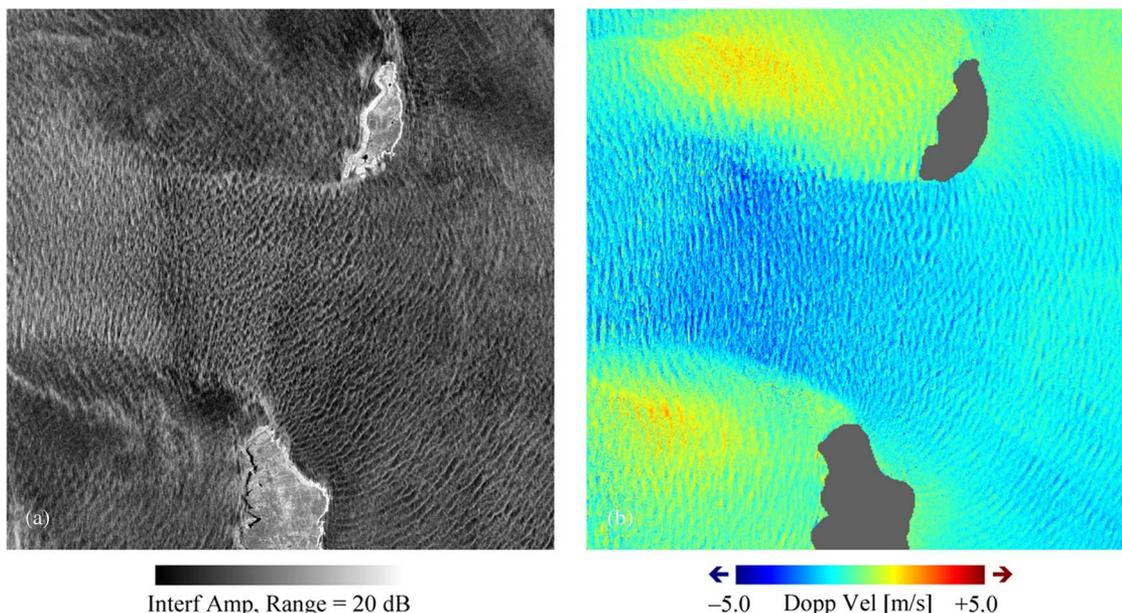

Fig. 4. Magnified subsections of Fig. 3(a) and (c) (February 26, 2012), showing wave signatures in the interferogram (a) amplitude and (b) phase converted into horizontal Doppler velocity. Here, the full-resolution data were averaged over grid cells of $8.40 \text{ m} \times 8.46 \text{ m}$ (5×4 samples per grid cell); area size $\approx 10 \text{ km} \times 10 \text{ km}$.

interferograms from April 26, 2010, and March 19, 2012. Homogeneous means in this context that we selected areas with very small spatial current variations, such that the rms variability of phases and Doppler velocities could be attributed to signal decorrelation and instrument noise effects, not to current variations. In both cases, suitable subimages for this purpose were found in the vicinity of the upper right corner of the frames shown in Figs. 2 and 3. We averaged the real and imaginary parts of the complex arrays in groups of 1, 2, 4, 8, ... up to 1024^2 samples and recomputed the corresponding phases after each step, such that the first step let us compute the rms phase variability of the 4096×4096 original pixel values, the second step of 2048×4096 values averaged over two pixels each, the third step of 2048×2048 , and the last step of $4 \times 4 = 16$ remaining averaged values. Finally, the rms phase variabilities were converted into horizontal Doppler velocity uncertainties. Results are shown in Fig. 5.

We have always assumed that desirable uncertainties of current measurements are on the order of 0.1 m/s or less. Fig. 5 shows that the rms variabilities derived from the DRA-mode and TanDEM-X data cross this level at approximately 300 000 and 300 samples, respectively. This means that one needs to average the full-resolution DRA-mode data over approximately 1 km^2 to reduce the residual noise to 0.1 m/s, while the TanDEM-X data provide the same accuracy after averaging over only $33 \text{ m} \times 33 \text{ m}$. This is quite impressive, and it confirms that further analysis of the wave patterns in Fig. 4 makes sense. Of course, one always has to take into account that SAR interferograms, like conventional SAR intensity images, are affected by SAR imaging artifacts such as velocity bunching and an azimuth cutoff of resolved wavenumbers [15], [16]. The problem of wave retrievals from ATI imagery was studied theoretically in [17]. Another important comment in this context is that the quoted accuracy or uncertainty of 0.1 m/s

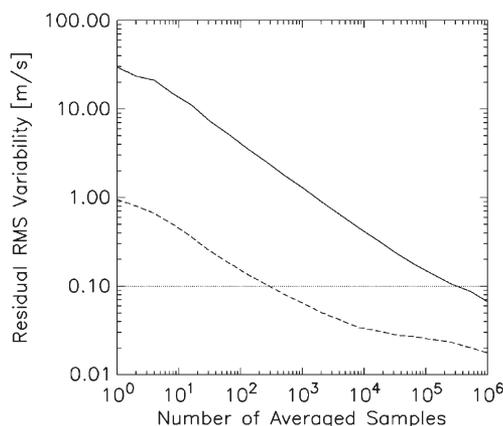

Fig. 5. Residual uncertainty (rms variability) of ATI-based line-of-sight Doppler velocities versus number of averaged samples, as obtained from homogeneous 4096×4096 pixel subarrays of the (solid line) full-resolution TerraSAR-X DRA-mode interferogram from April 26, 2010, and (dashed line) TanDEM-X interferogram from March 19, 2012.

is a measure of the remaining statistical noise only. ATI-derived currents will usually have an additional absolute error as a result of calibration uncertainties and suboptimal corrections for wave contributions, which cannot be reduced by averaging.

The results of our data quality analysis are consistent with the simulation-based findings in [10], but in comparing the results for the TerraSAR-X DRA-mode and TanDEM-X data with each other and with the theoretical findings, one has to take into account that the data were acquired under different wind and wave conditions and at different polarizations. Furthermore, the 4096×4096 pixel test array from the TanDEM-X data set had visible wave patterns and slight current variations in it, the latter of which cause the slope of the dashed line in Fig. 5 to decrease at large numbers of samples. This would not happen with data from a perfectly homogeneous area.

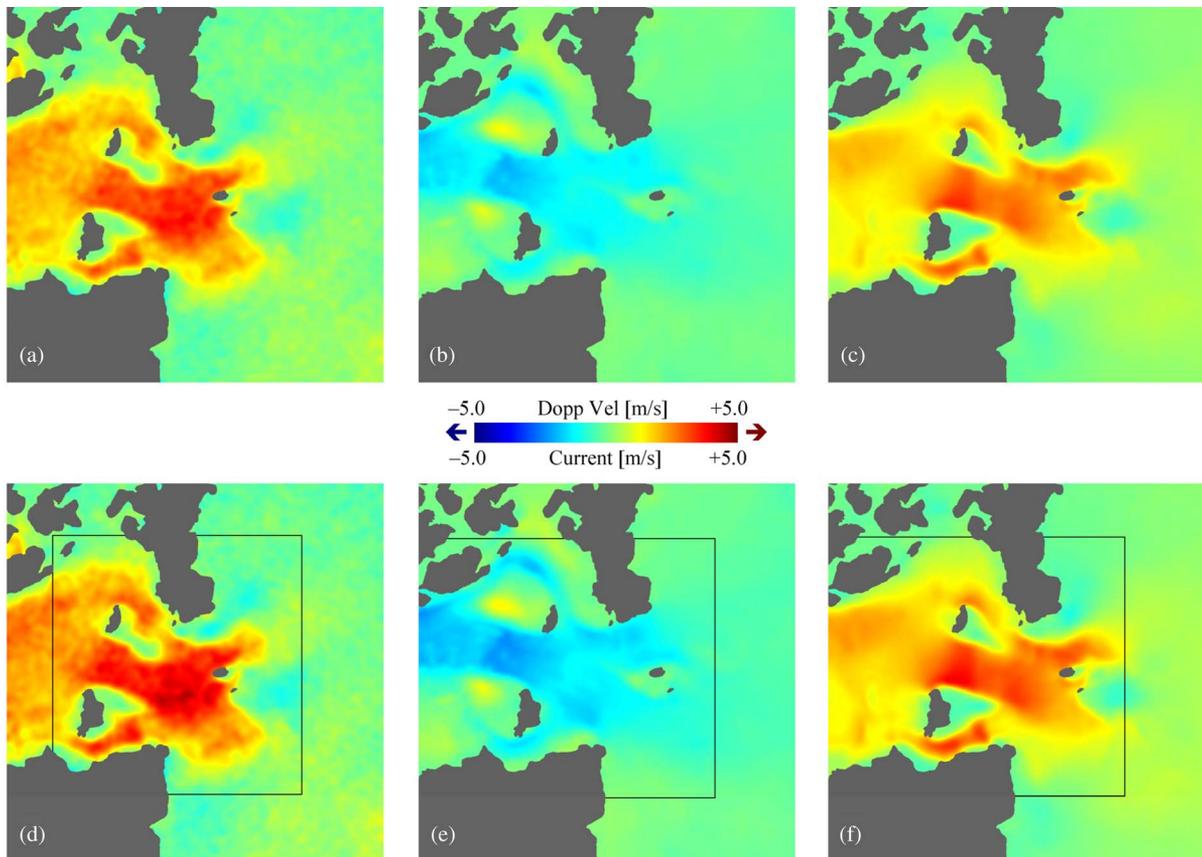

Fig. 6. (Top) Smoothed Doppler velocity and (bottom) corrected line-of-sight current fields derived from the data sets in Figs. 2 and 3. The black frames outline the coverage of the DCA results in Fig. 11.

D. Current Field Filtering and Correction

Obviously, the DRA-mode velocity field in Fig. 2(c) needs more spatial averaging to reduce noise, and the TanDEM-X velocity fields in Fig. 3(c) and (f) should be smoothed across the visible wave patterns to emphasize the underlying current field. In the case of the DRA-mode data, we have done the averaging by applying 11×11 element boxcar smoothing to the real and imaginary parts of the $25 \text{ m} \times 25 \text{ m}$ grid interferogram three times. Grid points for which the mean coherence in the surrounding 11×11 element window was smaller than 0.5 were excluded from this procedure, and the resulting gaps were filled by interpolation between the surrounding higher quality data. Smoothed phases and Doppler velocities were computed from the smoothed and quality-optimized real and imaginary part arrays. The result is shown in Fig. 6(a). For the TanDEM-X data, we used a similar smoothing method but with a directional weighting in the 11×11 element smoothing kernel that accounts for the local dominant wave pattern. This way, the smoothing focuses on the wave pattern while preserving a higher resolution in the direction parallel to the wave crests. Results are shown in Fig. 6(b) and (c). Note how the Doppler velocity field obtained for the March 19 case [Fig. 6(c)] looks clearly smoother than the one obtained for the DRA-mode case [Fig. 6(a)], which represents a similar tidal scenario. On February 26, 2012, the satellite overpass took place at a tidal phase with an opposite flow direction, which is visible in the current

field [Fig. 6(b)] as well as in the image intensity modulation patterns around the islands [compare Fig. 3(a) and (d)].

At this processing level, we have obtained relatively good-looking line-of-sight Doppler velocity arrays. Theoretically, they still include spatially varying contributions of wave motions [9], which should ideally be removed by an iterative modeling procedure, as demonstrated in [4]. However, this is difficult to do for such a relatively large test area with complicated current patterns and wind variations around several islands and an unknown current component perpendicular to the radar look direction. Fortunately, experience with the data analysis and numerical simulations in [4]–[7] has shown that the wave–current interaction effects are usually small. Therefore, we limit our corrections to wind-related wave modulation effects, estimating effective surface wind variations from the local current (which affects the relative wind acting on the moving water surface) and from image intensity variations. Corresponding variations of wave contributions to the local Doppler frequency were computed using the model described in [9] and subtracted. All resulting current fields were then recalibrated to satisfy the condition of zero mean currents at coastlines perpendicular to the radar look direction. Fig. 6(d)–(f) shows our resulting best estimates of the line-of-sight surface current fields in the three cases. The corrections for wind and wave effects tend to enhance the spatial variations in all three velocity fields, but not very much.

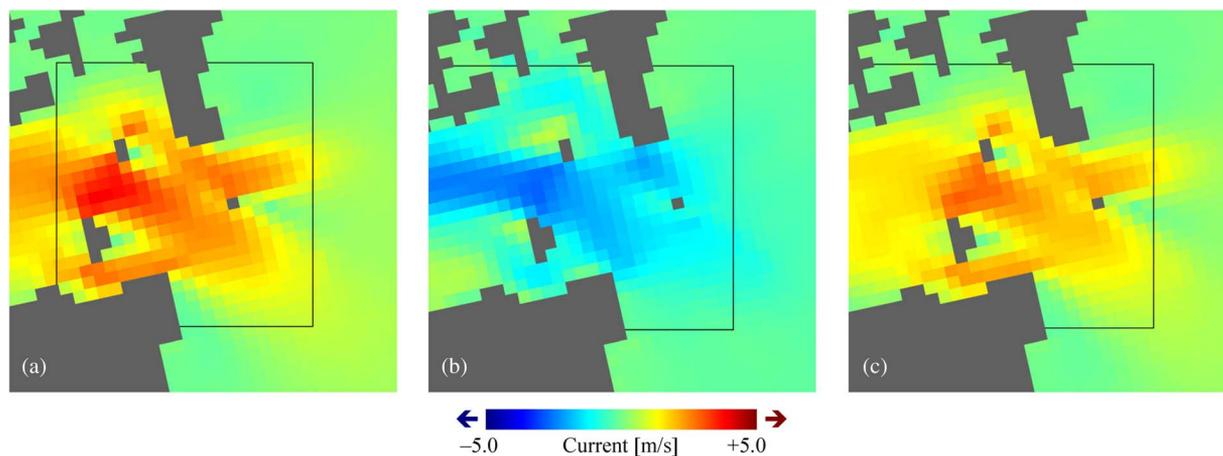

Fig. 7. Line-of-sight current fields in the test area from POLPRED for (a) April 26, 2010, (b) February 26, 2012, and (c) March 19, 2012, all 06:41 UTC.

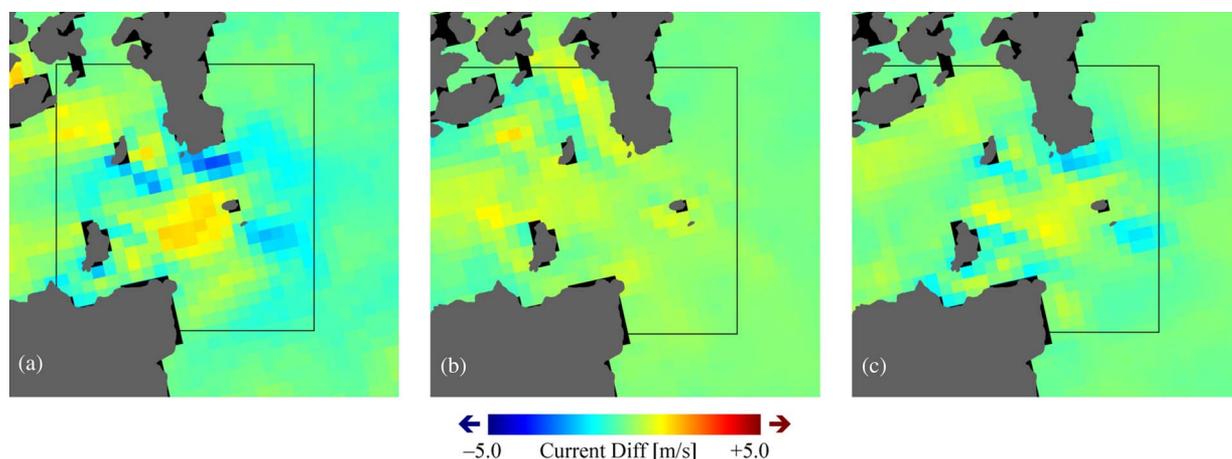

Fig. 8. Differences between the ATI-based current fields of Fig. 6 and the POLPRED current fields of Fig. 7, averaged over each $1 \text{ km} \times 1 \text{ km}$ grid cell of POLPRED. The red color indicates that the ATI-based current has a positive difference from the POLPRED current.

III. COMPARISON WITH CIRCULATION MODEL RESULTS

Reference current fields for the three satellite overpasses were obtained using the offshore tide computation system POLPRED of the National Oceanography Centre, Liverpool, U.K. POLPRED uses 26 harmonics derived from the 2-D high-resolution numerical circulation model CS3 [18] to estimate current fields at any time (i.e., tidal phase) of interest. With this setup, POLPRED can generate a model current field instantly, but it accounts neither for the specific wind scenario at the time of interest nor for possible differences between depth-averaged currents and surface currents. Furthermore, the spatial resolution of $1 \text{ km} \times 1 \text{ km}$ of POLPRED can cause unrealistic results in areas with strong depth variations on short spatial scales and complicated coastlines and islands, and it is not fine enough to validate variations in the TanDEM-X ATI-based current fields on shorter spatial scales. These limitations must be taken into account in the interpretation of differences between POLPRED- and ATI-based line-of-sight currents.

Fig. 7 shows the line-of-sight components of the POLPRED current fields for our three test scenarios. At first glance, the agreement with the ATI-based current fields at the bottom part of Fig. 6 is quite good. A closer look at the current fields and at the mean difference in each grid cell, shown in Fig. 8,

reveals that the ATI-based current field for April 26, 2010 [Fig. 6(d)] has the strongest currents further east than POLPRED [Fig. 7(a)] and that the westward POLPRED currents for February 26, 2012 [Fig. 7(b)] are stronger than the ones obtained from the TanDEM-X data [Fig. 6(e)]. For March 19, 2012 [Figs. 6(f) and 7(c)], we find a similar difference pattern as for April 26, 2010, but with less pronounced differences. The fact that positive and negative differences occur at the same locations in these two cases with similar flow conditions suggests that a systematic shortcoming of POLPRED or our data processing technique will always cause similar difference patterns at this tidal phase. We believe that the differences are partly due to an inaccurate and/or outdated bathymetry used in the numerical circulation model on which POLPRED is based. The model bathymetry must be based on various data sets from surveys that took place more than ten years ago, none of which would have been up to modern multibeam echo-sounding standards.

Fig. 9 shows the scatter diagrams and results of a statistical analysis, which was done for the regions marked by black rectangles in Figs. 6(d)–(f) and 7. They represent the regions for which DCA results are available as well, as discussed in Section IV. Like the current different maps in Fig. 8, the

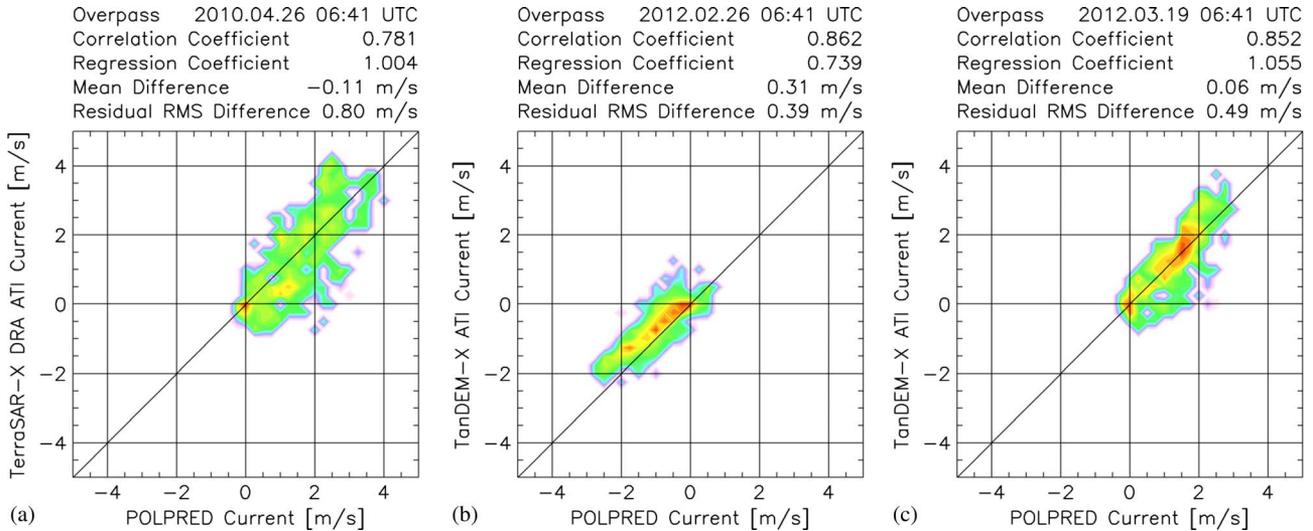

Fig. 9. Scatter diagrams of ATI-based versus POLPRED currents and statistical analysis results for the three cases.

statistical analysis was done for mean ATI-based currents in each POLPRED grid cell, such that there were no statistical asymmetries due to different spatial resolutions. We computed the shown correlation and regression coefficients, mean differences, and residual rms differences (i.e., rms differences after subtraction of the mean differences). The scatter diagrams and the statistical quantities indicate good general agreement. As could be expected, we find better correlation coefficients (0.862 and 0.852 versus 0.781) and smaller residual rms differences (0.39 and 0.49 m/s versus 0.80 m/s) for the two TanDEM-X-based products than for the TerraSAR-X DRA-mode product. However, the large residual rms difference in the DRA-mode case must be attributed to the discrepancies between spatial current variations [Fig. 8(a)]: According to the findings in Section II-C, the residual statistical uncertainty of the mean ATI-based currents in each POLPRED grid cell of $1 \text{ km} \times 1 \text{ km}$ should not be much larger than 0.1 m/s.

While regression coefficients and mean differences are very good in the April 26 and March 19 cases, the values for the February 26 case (regression coefficient = 0.739, mean difference = 0.31 m/s) and the scatter diagram in Fig. 9(b) show even more than the current difference map in Fig. 8(b) that we seem to observe a significantly less pronounced westward flow at the time of this satellite overpass than predicted by POLPRED. To investigate this further, we have compared this TanDEM-X-derived current field with POLPRED current fields for different times within an interval of ± 60 min around the nominal time of 6:41 UTC. We find best agreement with the current field for 7:21 UTC (40 min after the nominal time of the satellite overpass), where regression coefficient and mean difference improve to 0.999 and -0.04 m/s, respectively, and the residual rms difference improves from 0.39 to 0.34 m/s. Performing the same test for the two other cases for comparison, we find that the differences between ATI-based currents and POLPRED currents are almost constant for about 50 and 30 min after the satellite overpasses, respectively. This lets us conclude that the observed surface current fields may be ahead of the POLPRED current fields by approximately 30–40 min, possibly as a result of specific wind conditions, seasonal effects,

or general shortcomings of the numerical model on which POLPRED is based. Differences between surface currents and depth-averaged currents are another possible explanation—note that the February 26, 2012, scenario is the only one with a wind component against the current, which may reduce the current close to the surface. However, we do not have sufficient experience with spaceborne ATI-based current fields to rule out shortcomings of our data processing techniques as another potential source of discrepancies. Fig. 10 shows the scatter diagrams and statistical quantities for the three ATI-based current fields versus POLPRED results for 7:31, 7:21, and 7:11 UTC, respectively, instead of 6:41 UTC. The spatial distributions of current differences at these alternate times look still similar to the ones found with the POLPRED current fields for 6:41 UTC (Fig. 8) and are not shown explicitly.

IV. COMPARISON WITH DCA RESULTS

Within the last decade, the technique of DCA of single-antenna SAR data has been established as a promising alternative to ATI. Following ideas from the late 1970s [19] and a first demonstration with European Remote Sensing Satellite-1 (ERS-1) SAR data in 2001 [20], Chapron and coworkers in France and Norway picked up the idea and presented very interesting results in [21] in 2005 and continued to refine their technique and to apply it to a variety of scenarios in the following years (e.g., [22]–[24]). In contrast to ATI, the DCA technique uses data from a single SAR antenna only, such that it can be applied to a wide range of existing SAR data sets without specific preparations. It exploits differences between Doppler frequencies estimated from the data within the SAR processor and theoretical values based on the imaging geometry and the relative motion between satellite and rotating Earth. The Doppler estimation must be performed within a window, thus at a final spatial resolution much lower than the resolution of a fully processed SAR image, but the quality of DCA results has been found to be comparable to the quality of divided-antenna mode ATI results from TerraSAR-X. A qualitative comparison of both techniques was presented in [25].

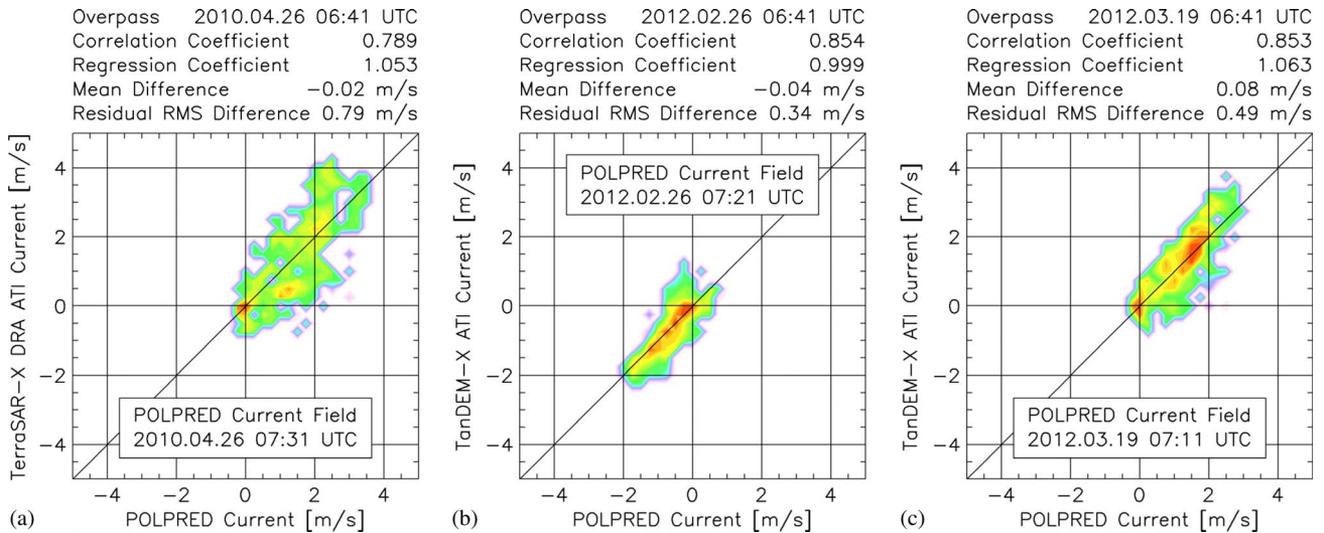

Fig. 10. Same as Fig. 9, but using POLPRED current fields for later times (as indicated in the boxes) that were found to agree better (case b) or about as well as the ones for 06:41 UTC (cases a and c) with the ATI-based current fields.

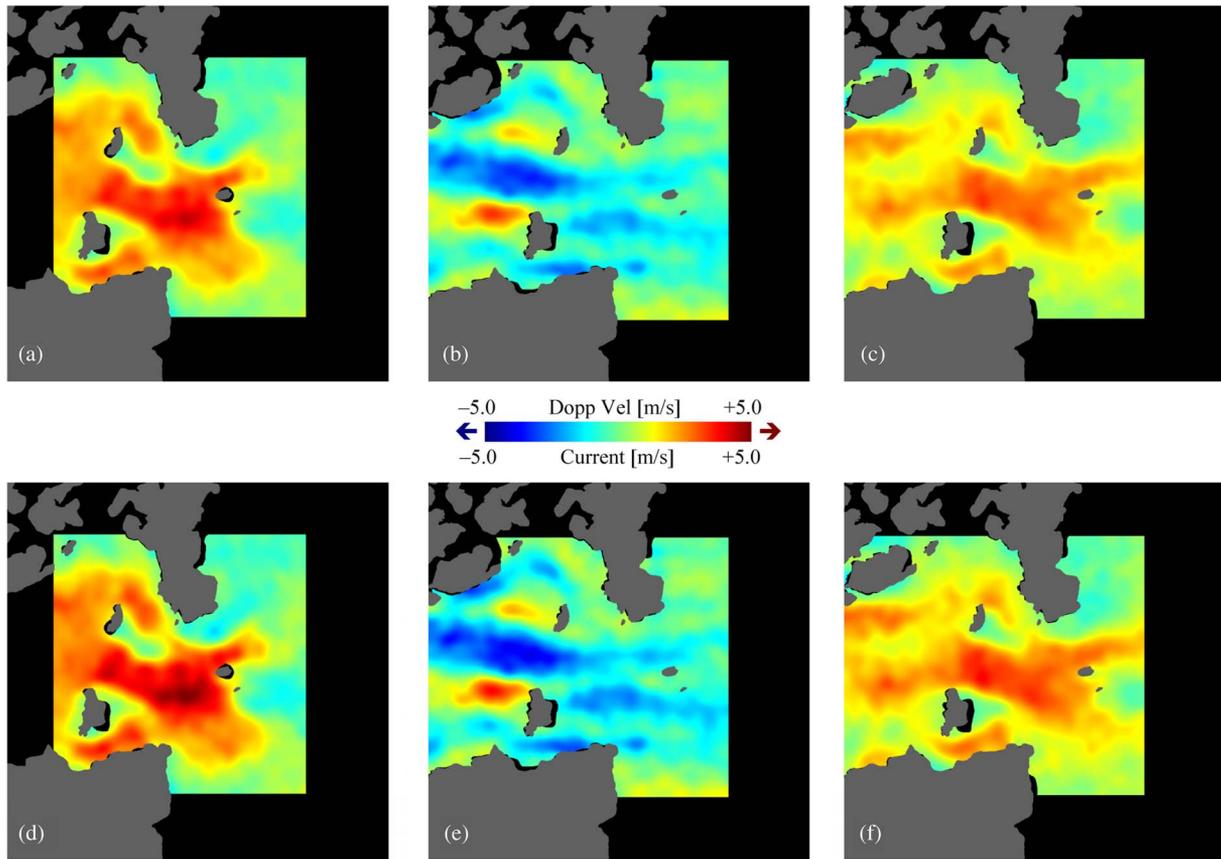

Fig. 11. Same as Fig. 6, but for DCA- instead of ATI-based Doppler velocity and current fields.

A demonstration of DCA with TerraSAR-X data was given in [26], but so far, no direct comparison of ATI and DCA results based on the same raw data set has been presented in the literature. Such a comparison is particularly interesting if it can be done with InSAR data acquired at short and near-optimum AT baselines, such as the data considered in this work. Because of this, we decided to apply the techniques in [26] to our three cases and to perform another comparison of the results with the POLPRED current fields, as well as a direct comparison of

ATI- and DCA-based Doppler velocity fields. The window used for the spectral estimation is composed of 256×256 pixels, thus covering about 500 m in the azimuth direction and 250 m in range. The estimation is performed every 50 pixels, and the final velocity map is derived using a cubic interpolation and additional smoothing.

Fig. 11(a)–(c) show the three Doppler velocity fields obtained from DCA, using the sum signal from the two TerraSAR-X antenna halves in the DRA-mode case and the

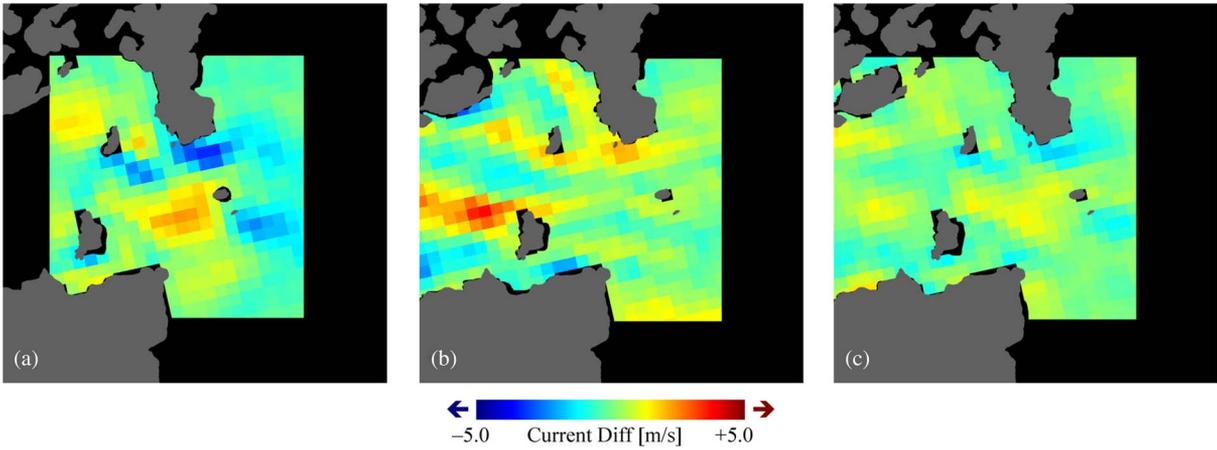

Fig. 12. Same as Fig. 8, but for differences between the DCA-based current fields in Fig. 11(d)–(f) and the POLPRED current fields.

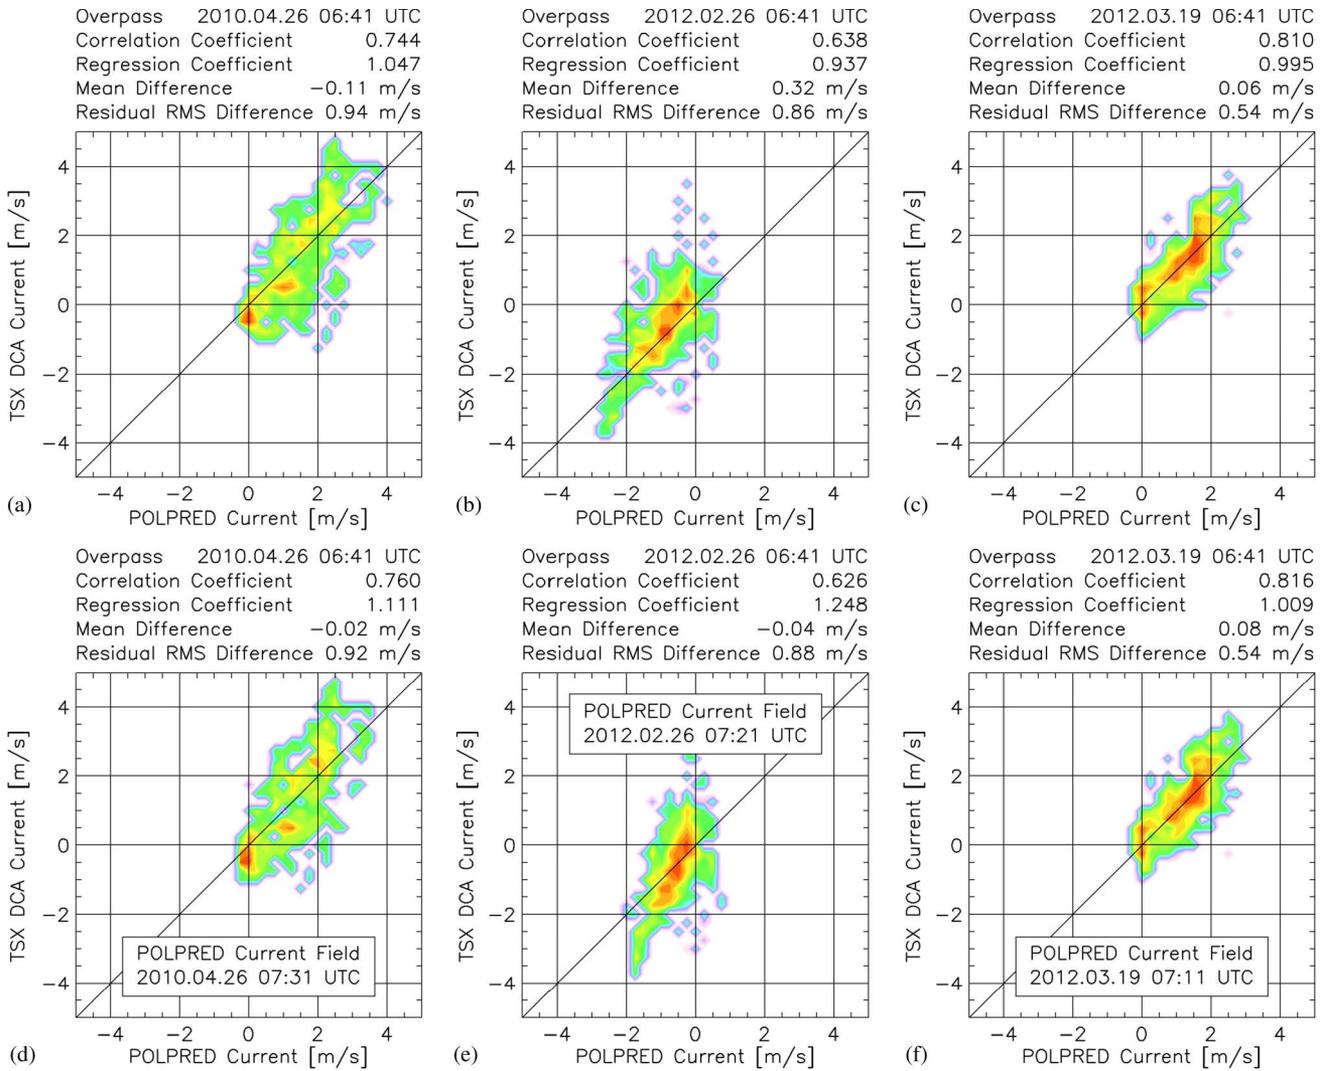

Fig. 13. Same as Figs. 9 and 10 combined, but for DCA- instead of ATI-based currents versus POLPRED currents.

signal from the master satellite (i.e., the one in monostatic operation) in the two TanDEM-X cases. While this processing could have been done for the complete scenes, it was decided to limit it to the region of strongest currents in the center of the test area, which cause the most significant Doppler variations. As already mentioned, the absolute calibration was forced to

match the absolute calibration of the ATI results, i.e., the mean values are the same. Like the SAR raw data processing and interferogram generation, the DCA processing was performed at DLR, while some additional smoothing and the calibration adjustment were done at the University of Miami, as well as an application of corrections for wind and wave effects in the same

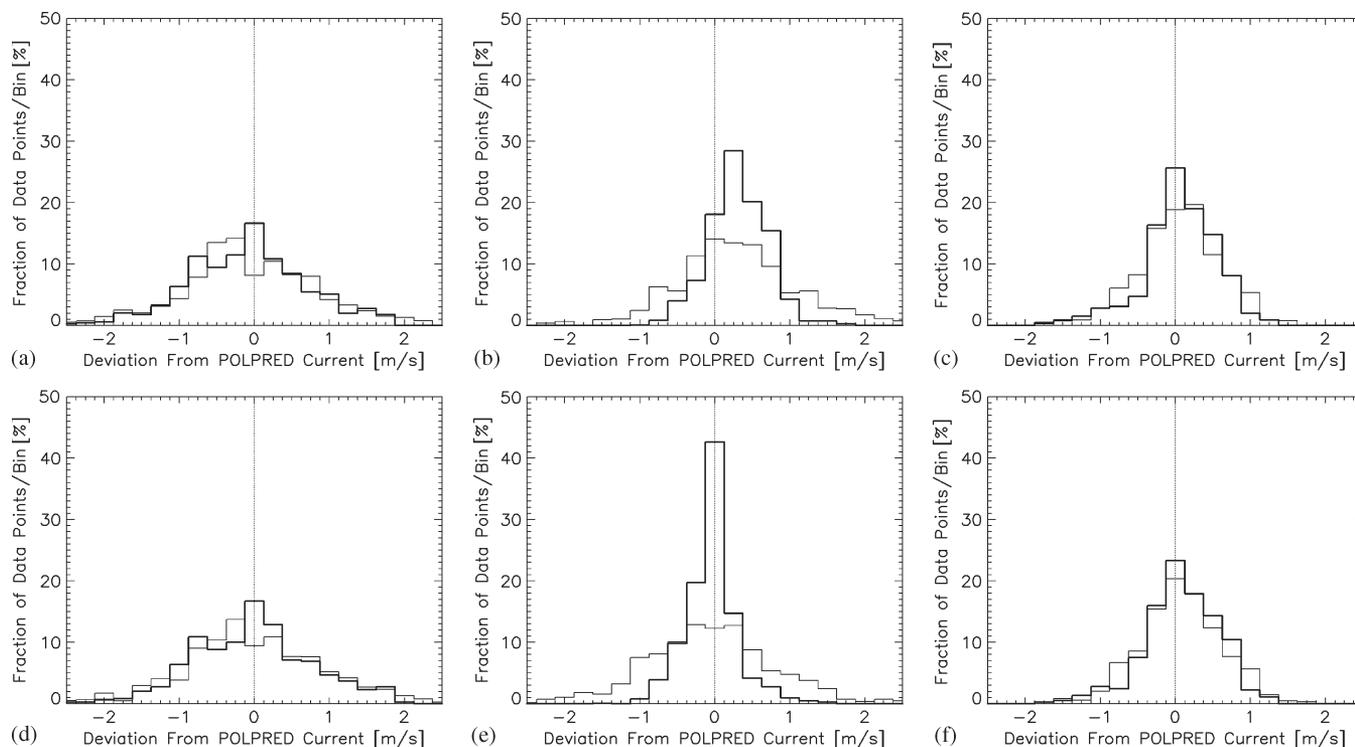

Fig. 14. Histograms of deviations of the (thick line) ATI- and (thin line) DCA-based currents from the POLPREd currents, for the three considered cases (columns) and using POLPREd currents for (top row) 6:41 UTC and (bottom row) alternate times. The height of each histogram bar shows the percentage of data points in the corresponding bin with a width of 0.25 m/s.

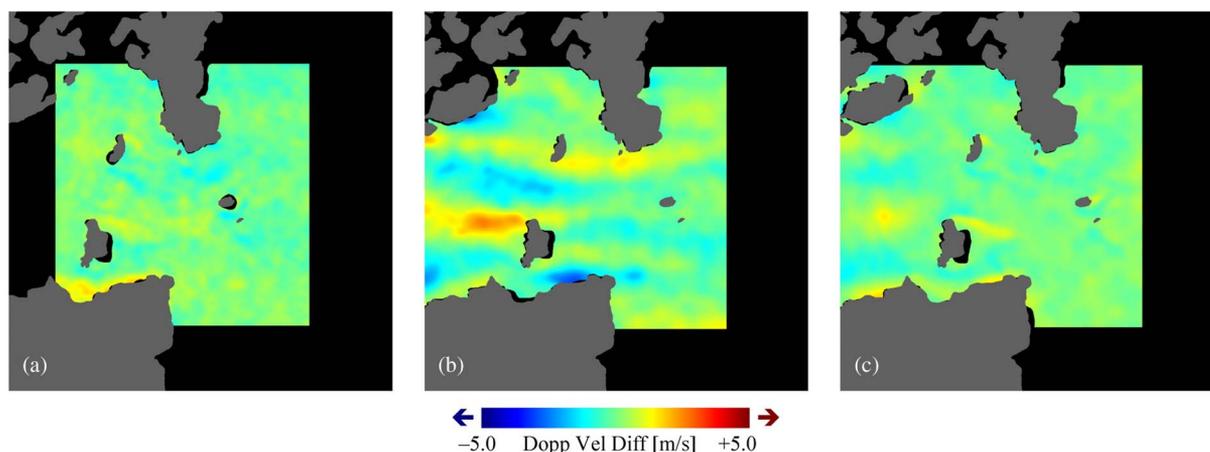

Fig. 15. Same as Figs. 8 and 12, but for differences between the DCA- and ATI-based Doppler velocity fields of Figs. 11 and 6 on a $25 \text{ m} \times 25 \text{ m}$ grid.

way as it had been done for the ATI data. The resulting current fields are shown in the bottom row of Fig. 11. Differences from the model current fields in Fig. 7 are shown in Fig. 12.

As could be expected, the DCA-based current fields and their differences from the model current fields do not look much different from the ATI results, except for the February 26 case, where the DCA-based current field exhibits significantly stronger currents with much more pronounced spatial variations [compare Figs. 11(e) and 6(e)]. Scatter diagrams and statistical properties are shown in Fig. 13, using POLPREd current fields for 6:41 UTC in the top row and the alternate ones for 7:31, 7:21, and 7:11 UTC, respectively, in the bottom row, like in Figs. 9 and 10. The statistical quantities indicate a somewhat reduced data quality compared to the ATI results. In the February 26 case (the center column of Fig. 13), the strong spa-

tial variations in the DCA-based current field agree better with the POLPREd current field for 6:41 UTC than with the one for 7:21 UTC, but we do not think that this justifies the conclusion that something may be wrong with the ATI results, since the spatial variations in the POLPREd current field agree clearly better with the ones in the ATI-based current field than the ones in the DCA-based current field [compare Figs. 8(b) and 12(b)]. Fig. 14 shows the histograms of deviations of the ATI- and DCA-based currents from the POLPREd currents. For all considered cases, the DCA-based currents have a larger percentage of large deviations from POLPREd than the ATI-based ones.

Note that the quality of the DCA current field obtained for the DRA-mode case (left columns of Figs. 11 and 13) is almost as good as the quality of the corresponding ATI result (left columns of Figs. 6, 9, and 10). The DCA result for March 19

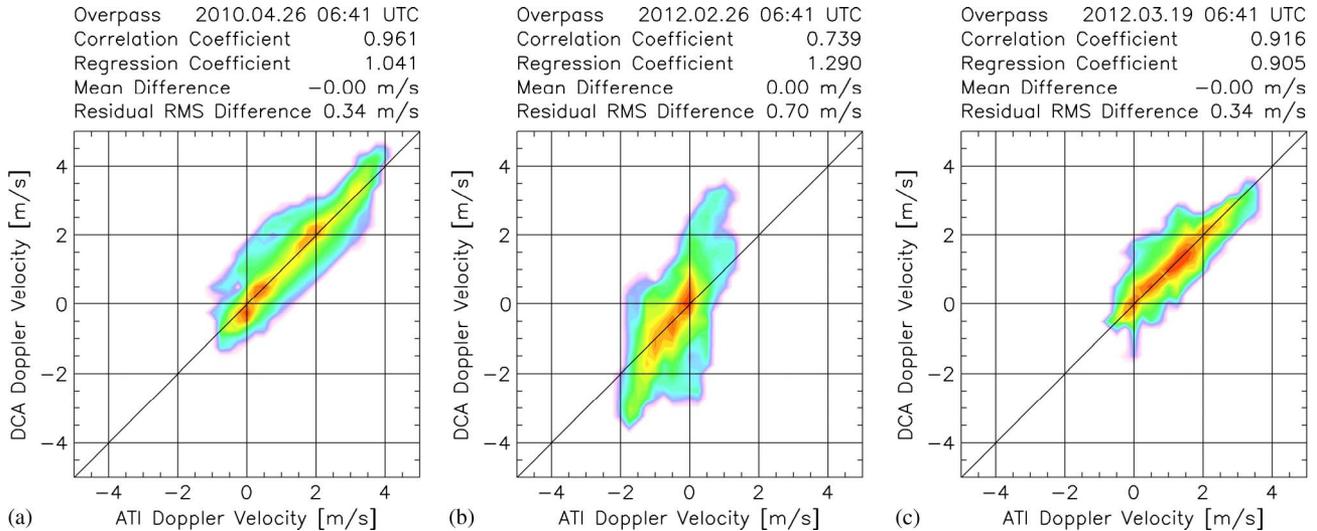

Fig. 16. Same as Fig. 9, but for DCA- versus ATI-based Doppler velocities.

(right columns of Figs. 11 and 13) is of even better quality, almost as good as the ATI result obtained with a near-optimum baseline. Of course, this is valid at the $1 \text{ km} \times 1 \text{ km}$ grid resolution of POLPRED only, while we demonstrated in Section II-C that the effective spatial resolution of the TanDEM-X ATI-based velocity fields is much higher. The DCA-based current fields cannot match the high resolution of TanDEM-X ATI products due to limitations imposed by the window processing.

Finally, Fig. 15 shows the differences between the DCA- and ATI-based Doppler velocity fields (top rows of Figs. 11 and 6), and Fig. 16 shows the corresponding scatter diagrams and statistical quantities. For this analysis, the $25 \text{ m} \times 25 \text{ m}$ grid data were used without further resolution reduction, i.e., no averaging over the $1 \text{ km} \times 1 \text{ km}$ grid cells of POLPRED. We find good agreement with correlation coefficients of 0.961 and 0.916 and residual rms differences of 0.34 m/s for the first and the last case, but more pronounced differences and less convincing statistical properties (correlation coefficient = 0.739, regression coefficient = 1.290, and residual rms difference = 0.70 m/s) for the February 26 case. It is not clear what causes this poor agreement, but the comparisons with POLPRED suggest that it can be attributed to anomalies in the DCA-derived current field rather than to a problem with the ATI result. Since the DCA processing was a specifically requested voluntary contribution, we do not have the resources to study the problem in more detail within the framework of this work.

V. CONCLUSION AND OUTLOOK

For the first time, we have been able to test and demonstrate ocean current measurements by spaceborne InSAR at near-optimum AT baselines of about 25 and 40 m, using TanDEM-X data from February/March 2012, when a temporarily available formation geometry permitted such measurements in a latitude band including the northern North Sea and our test site, the Pentland Firth. For comparison, we included a TerraSAR-X DRA-mode data set in the analysis, as well as current fields derived from single-antenna data using the DCA technique.

Reference current fields were taken from the numerical tide computation system POLPRED.

We were able to show that the rms variability of TanDEM-X-derived velocities at these baselines gets better than 0.1 m/s after averaging over just $33 \text{ m} \times 33 \text{ m}$ (versus about $1000 \text{ m} \times 1000 \text{ m}$ for the short-baseline DRA-mode data), which makes it possible to resolve orbital motions of long surface waves. All ATI-based current fields showed good agreement with the corresponding POLPRED current fields, but the results obtained for the February 26, 2012, case suggest that POLPRED may be lagging behind the observed surface currents by approximately 30–40 min. In the other two cases, the POLPRED current fields are almost constant for 30–50 min after the TerraSAR-X/TanDEM-X overpass time, such that a similar time lag between model and observations may be present on those days. Alternatively, the problem may be related to differences between surface currents and depth-averaged currents or other shortcomings of the model physics, or to suboptimal ATI data processing. This could not be decided within the framework of this work, but we think that our results demonstrate the advantages and the potential of ATI at near-optimum baselines quite well despite the open questions.

The DCA-based current fields are less accurate than the ATI-based ones and seem to exhibit unrealistically strong spatial variations in the February 26, 2012, case, but the other two DCA results are almost as good as the ATI results when compared with the POLPRED current fields at $1 \text{ km} \times 1 \text{ km}$ resolution. This confirms that DCA is a promising current retrieval technique for cases that do not require the highest possible spatial resolution. Furthermore, together with the finding that the effective spatial resolution of our DRA-mode data is not much better than $1 \text{ km} \times 1 \text{ km}$, one can conclude that DCA can deliver current fields of almost the same quality as ATI in the short-baseline DRA and AS modes of TerraSAR-X for many applications. Only in cases that require high spatial resolution in a particular direction, such as current measurements in rivers or over oceanic internal waves, short-baseline ATI will have an advantage over DCA because it permits accurate

land masking and nonisotropic averaging/smoothing of full-resolution interferograms.

In the coming months, we will analyze the wave signatures in existing ATI data in more detail and check if the coherence of TanDEM-X data at various AT baselines is consistent with theoretical predictions. Furthermore, we will try to acquire additional TanDEM-X data at near-optimum baselines and to obtain higher resolution reference current fields for a more detailed analysis of short-scale spatial variations. There is a good chance that suitable orbit geometries for current measurements will be made available more frequently when the main mission objectives of TanDEM-X have been accomplished, such that many science users can benefit from the high data quality and from the data processing experiences gained from activities such as the ones described in this paper. TanDEM-X may be ready for this in 2014.

ACKNOWLEDGMENT

The copyright for TerraSAR-X and TanDEM-X data used in this paper is with the German Aerospace Center (DLR). TanDEM-X data were obtained through TanDEM-X science project ATI-OCEA0599 (Principal Investigator: H. Runge).

Roland Romeiser (M'00) received the Dipl.-Phys. degree from the University of Bremen, Bremen, Germany, in 1990 and the Dr.rer.nat. and Habilitation degrees from the University of Hamburg, Hamburg, Germany, in 1993 and 2007, respectively.

From 1990 to 1998, he was a Project Scientist with the Institute of Oceanography, University of Hamburg, where he was a permanent Staff Scientist from 1999 to 2009. From August 1998 to July 1999, he spent a year with the Applied Physics Laboratory, Johns Hopkins University, Laurel, MD, USA, as a Feodor Lynen Fellow of the Alexander von Humboldt Foundation. Since April 2008, he has been an Associate Professor with the Rosenstiel School of Marine and Atmospheric Science, University of Miami, Miami, FL, USA. He has a wide experience in the field of remote sensing of ocean currents, waves, and winds by airborne and spaceborne microwave radars. He has been involved in many international remote sensing projects and experiments in this field and authored and coauthored 28 peer-reviewed journal articles and 69 conference articles and book contributions and organized and chaired several sessions at international remote sensing conferences. His research interests focus on the theoretical modeling of microwave radar signatures of ocean features and on the development and evaluation of new and improved techniques for current and wave measurements by conventional and interferometric synthetic aperture radar.

Dr. Romeiser has been an Associate Editor of the IEEE JOURNAL OF OCEANIC ENGINEERING since fall of 2000.

Hartmut Runge received the Dipl.-Ing. degree in electrical engineering/communications from the University of Siegen, Siegen, Germany, in 1980.

Since that time, he has been a Staff Member with the German Aerospace Center (DLR), Oberpfaffenhofen, Germany, working on various aspects of synthetic aperture radar (SAR) data processing and applications. He was the Systems Engineer for the Processing and Archiving Facility for the X-SAR missions in 1996 and the Project Manager of the X-SAR data processing subsystem for the Shuttle

Radar Topography Mission (SRTM) in 2000. Furthermore, he was the Principal Investigator for the SRTM along-track interferometry (ATI) experiments, and he pioneered the measurement of moving objects like cars and ocean currents from a spaceborne sensor. He worked on concepts for a close satellite formation flight for ATI. For six months, he worked in the Toulouse Space Centre of the Centre National d'Études Spatiales (CNES) for the Cartwheel project and formed a joint DLR/CNES Research Team. He initiated the implementation of an ATI mode on TerraSAR-X and is currently the Project Manager of the TerraSAR-X Traffic Monitoring Project.

Steffen Suchandt received the Dipl.-Ing. degree in electrical engineering from the University of Rostock, Rostock, Germany, in 1995.

From 1996 to 1998, he worked in the field of biomedical engineering. Since 1998, he has been a Scientific Employee with the Remote Sensing Technology Institute, German Aerospace Center (DLR), Oberpfaffenhofen, Germany, where he has been working on numerous aspects of interferometric synthetic aperture radar (SAR) processing. He was engaged in data calibration, processor development,

and digital elevation model processing of the Shuttle Radar Topography Mission. His current work is focused on the design and development of an automatic traffic information extraction system for TerraSAR-X data. Further activities include research on inland river current measurements using airborne SAR. He has a wide experience in SAR interferometry, ground moving-target indication, signal processing, and software development.

Ralph Kahle received the Dipl.-Ing. degree in aerospace engineering from the Technical University of Dresden, Dresden, Germany, in 2001, and the Dr.-Ing. degree from the Technical University of Berlin, Berlin, Germany, in 2005.

In 2004, he joined the German Space Operations Center, German Aerospace Center (DLR), Oberpfaffenhofen, Germany, as a Flight Dynamics (FD) Engineer. He is responsible for the TerraSAR-X/TanDEM-X FD system engineering and operation. His field of work also comprises space mission anal-

ysis, FD software development, and execution of Launch and Early Orbit Phase and routine FD operations.

Cristian Rossi received the Laurea Magistrale (M.Sc.) degree in telecommunication engineering from Politecnico di Milano, Milan, Italy, in 2006, with a thesis on azimuth antenna pattern estimation from synthetic aperture radar (SAR) data.

From 2006 to 2008, he was a Project Engineer with Aresys s.r.l.—a Politecnico di Milano spin-off company—being mainly involved in Sentinel-1 European Space Agency projects. Since 2008, he has been with the SAR Signal Processing Department, Earth Observation Center, German Aerospace Center

(DLR), Oberpfaffenhofen, Germany, where he works on interferometry algorithms for the TanDEM-X mission. His current research interests focus on urban remote sensing, data fusion, and Doppler shift estimation for ocean currents.

Paul S. Bell received an Honors degree in physics and electronics from the School of Physics and Astronomy, University of St. Andrews, St. Andrews, U.K., in 1992 and the Ph.D. degree from the School of Ocean Sciences, University of Wales Bangor, Bangor, U.K., in 2005, with a dissertation on the remote determination of bathymetric changes using ground-based radar.

Since 1992, he has been with the National Oceanography Center (previously known as the Proudman Oceanographic Laboratory), Liverpool,

U.K., developing a variety of acoustic and radar techniques to study flow and sediment dynamics at coastal sites. He is currently working on the use of ground-based remote sensing to map bathymetry, currents, and other hydrodynamic properties at marine renewable energy sites.
